

Logistic regression

Michael Friendly
Psych 6136

http://friendly.github.io/psy6136

Today's topics

- Model-based methods: Overview
- Logistic regression: one predictor, multiple predictors, fitting
- Visualizing logistic regression
- Effect plots
- Case study: Racial profiling
- Model diagnostics

Model-based methods: Overview

Structure

- Explicitly assume some probability distribution for the data, e.g., binomial, Poisson, ...
- Distinguish between the systematic component— explained by the model— and a random component, which is not
- Allow a compact summary of the data in terms of a (hopefully) small number of parameters

Advantages

- Inferences: hypothesis tests and confidence intervals
- Can test individual model terms (anova ())
- Methods for model selection: adjust balance between goodness-of-fit and parsimony
- Predicted values give model-smoothed summaries for plotting
- Interpret the fitted model graphically

loglm() vs. glm()

With loglm() you can only test overall fit (anova()) or difference between models (Lrstats())

What we can say:

Even the model with all pairwise associations fits poorly (2)

Comparing models with anova () and LRstats ()

```
> anova(berk.mod1, berk.mod2, test="Chisq")
LR tests for hierarchical log-linear models
Model 1:
~Dept * (Gender + Admit)
Model 2:
~ (Admit + Dept + Gender) ^2
        Deviance df Delta(Dev) Delta(df) P(> Delta(Dev)
Model 1 21.74 6
                                    1 0.21593
Model 2 20.20 5 1.531
                      20.204 5
Saturated 0.00 0
                                            0.00114
> LRstats(berk.mod1, berk.mod2)
Likelihood summary table:
        AIC BIC LR Chisq Df Pr(>Chisq)
berk.mod1 217 238 21.7 6
                              0.0014 **
berk.mod2 217 240 20.2 5 0.0011 **
Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 '' 1
```

Q: What can we say from this?

loglm() vs. glm()

With glm() you can test individual terms using anova() or car::Anova()

```
> berkeley <- as.data.frame(UCBAdmissions)</pre>
> berk.glm2 <- glm(Freq ~ (Dept+Gender+Admit)^2, data=berkeley,
                 family="poisson")
> anova(berk.glm2, test="Chisq")

Q: Can someone help interpret the term for Gender:Admit?

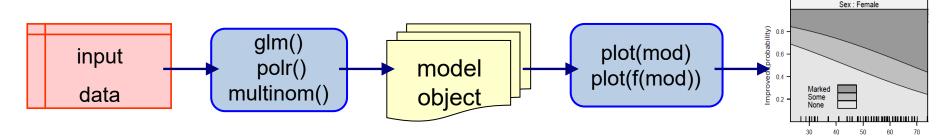

Dropping & adding terms

A useful strategy for model-building is to start with some model, and consider

- The effect of dropping high-order terms, one at a time
- The effect of adding terms w/in the scope of a larger model, one at a time
- MASS:dropterm() and MASS::addterm() do this for both glm() and loglm() models

Fitting & graphing models: Overview

Object-oriented approach in R:

- Fit model (obj <- glm(...)) → a model object
 </p>
- print (obj) and summary (obj) → numerical results
- anova (obj) and Anova (obj) → tests for model terms
- update(obj), add1(obj), drop1(obj) for model selection

Plot methods:

- plot (obj) often gives diagnostic plots
- Other plot methods:
 - Mosaic plots: mosaic (obj) for "loglm" and "glm" objects
 - Effect plots: plot (Effect (obj)) for nearly all linear models
 - Influence plots (car): influencePlot (obj) for "glm" objects

Modeling approaches: Overview

Association models

- Loglinear models
 (contingency table form)
 [Admit][Gender Dept]
 [Admit Dept][Gender Dept]
 [AdmitDept][AdmitGender][GenderDept]
 - Poisson GLMs
 (Frequency data frame)
 Freq ~ Admit + Gender * Dept
 Freq ~ Admit*Dept + Gender*Dept
 Freq ~ Admit*(Dept + Gender) +
 Gender*Dept
- Ordinal variables
 Freq ~ right + left + Diag(right, left)
 Freq ~ right + left + Symm(right, left)

Response models

- Binary response
- Categorical predictors: logit models logit(Admit) ~ 1 logit(Admit) ~ Dept logit(Admit) ~ Dept + Gender
- Continuous/mixed predictors
- Logistic regression models
 Pr(Admit) ~ Dept + Gender + Age + GRE
- Polytomous response
- Ordinal: proportional odds model
 Improve ~ Age + Sex + Treatment
- General multinomial model
 WomenWork ~ Kids + HusbandIncome

Logistic regression

Response variable

- Binary response: success/failure, vote: yes/no
- Binomial data: x successes in n trials (grouped data)

```
glm(success ~ ..., family=binomial)
glm(cbind(Nsuccess, Nfail) ~ ..., family=binomial)
```

Explanatory variables

- Quantitative regressors: age, dose
- Transformed regressors: √age, log(dose)
- Polynomial regressors: age², age³, · · · (or better: splines)
- Categorical predictors: treatment, sex (dummy variables, contrasts)
- Interaction regessors: treatment × age, sex × age

This is exactly the same as in classical ANOVA, regression models

Logistic regression: Extensions

Response variable

- Binary response: success/failure, vote: yes/no
- Binomial data: x successes in n trials (grouped data)
- Ordinal response: none < some < severe depression
- Polytomous response: vote Liberal, Tory, NDP, Green

Extensions of the framework for logistic regression allow us to handle more than two discrete outcomes. Explanatory variable remain the same

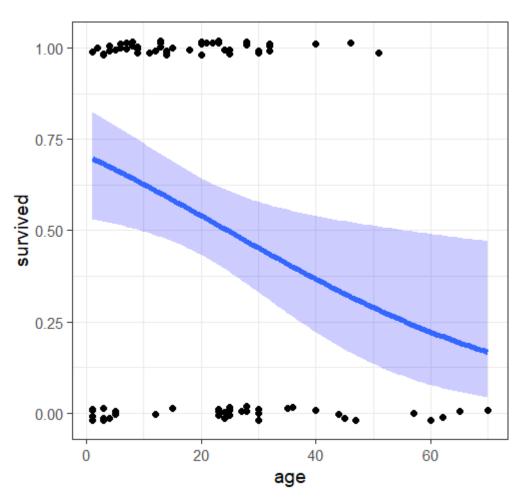

Explanatory variables

- Quantitative regressors: age, dose
- Transformed regressors: √age, log(dose)
- Polynomial regressors: age², age³, · · · (or better: splines)
- Categorical predictors: treatment, sex (dummy variables, contrasts)
- Interaction regessors: treatment × age, sex × age

This is exactly the same as in classical ANOVA, regression models

Survival in the Donner Party

Data on the Donner Party records the fate of 90 people who set out to CA in 1846. They were trapped in an early winter storm near Reno, NV. Only 48 survived.

Who survived? Why?

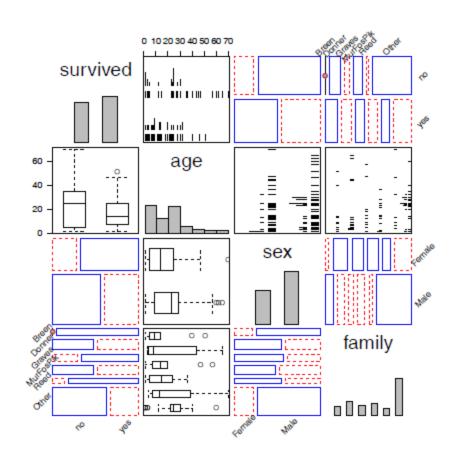

Logistic regression can model the probability of the binary (0/1) outcome of survival

A quantitative predictor like age gives predicted probabilities (& CI)

Other predictors – sex, family, ... can give a more detailed understanding

Survival in the Donner Party

- Binary response: survived
- Categorical predictors: sex, family
- Quantitative predictor: age
- Q: Is the effect of age linear?
- Q: Are there interactions among predictors?
- This is a generalized pairs plot, with different plots for each pair

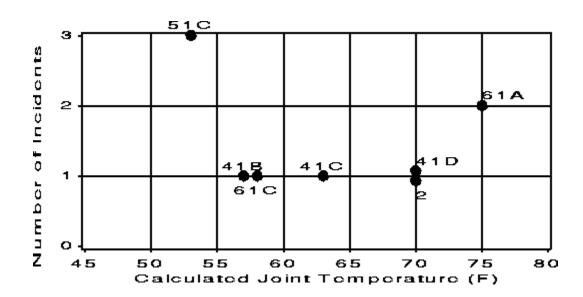

Some possible models:

```
glm(survived ~ age, data=Donner, family=binomial)
glm(survived ~ age + sex + family, data=Donner, family=binomial)
glm(survived ~ age * sex, data=Donner, family=binomial)
```

Challenger: A dataviz disaster

- The space shuttle Challenger exploded 73 sec. after takeoff on January 28, 1986, killing all 7 crew
 - Subsequent investigation revealed the proximal cause: Low temperature → failures of the rubber O-rings joining rocket stages
 - The anterior cause was a failure of data analysis & visualization
- Data: 24 previous flights: temperature, # of "incidents"

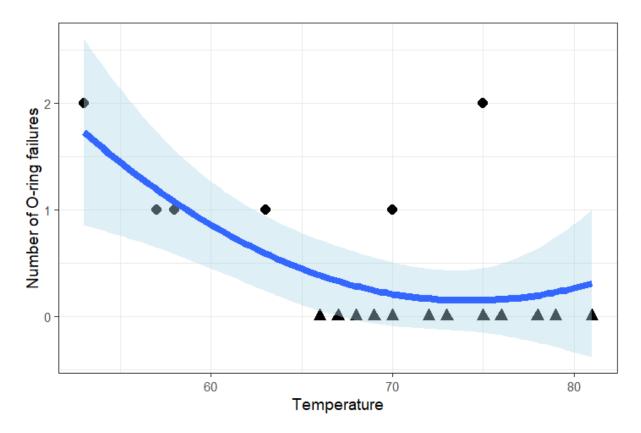

Morton-Thiokol engineers prepared this bad graph

But, they also excluded all flights where there was no damage

Challenger: A better graph

This graph plots the number of failures out of 6 O-rings in all previous flights, including those with 0 failures

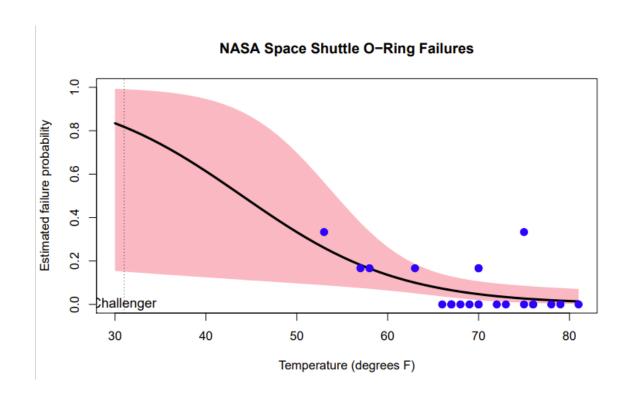

- It fits a simple quadratic regression, nFailures ~ poly(Temperature, 2)
- It should have been a warning that failures increase as temperature gets lower
- But it doesn't take into account that nFailures ~ Bin(p, n=6)

Challenger: A better analysis

Logistic regression treats the # failures as a binomial outcome with n = 6 trials The model provides

- Predicted probabilities outside the range of the data
- Confidence intervals, to judge model uncertainty

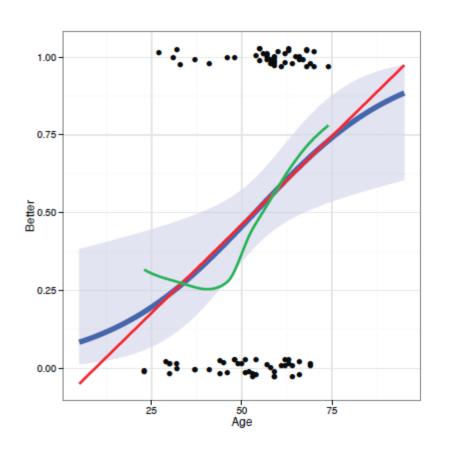

When the challenger was launched, the temp was 31° F

The CI band is very wide, but the predicted value is uncomfortably high

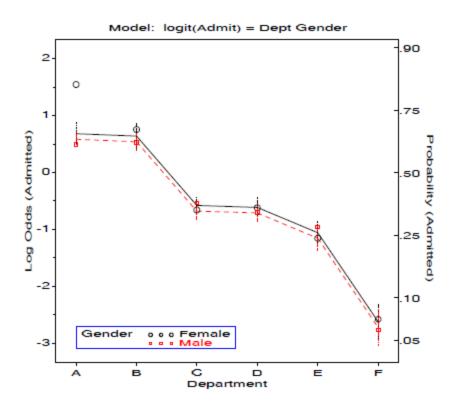

This analysis & graph might have saved lives!

Example: Arthritis treatment

- The response variable, Improved is ordinal: "None" < "Some" < "Marked"</p>
- A binary logistic model can consider just Better = (Improved>"None")
- Other important predictors: Sex, Treatment
- Main Q: how does treatment affect outcome?
- How does this vary with Age and Sex?
- This plot shows the binary observations, with several model-based smoothings

Example: Berkeley admissions

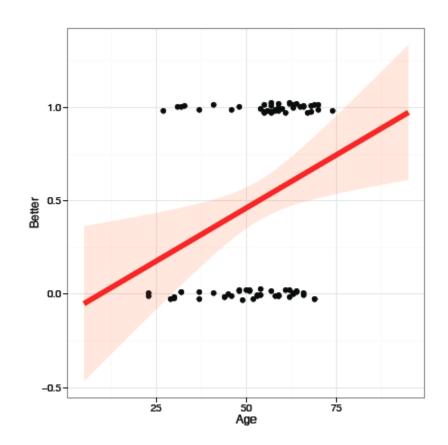

- Admit/Reject can be considered a binomial response for each Dept and Gender
- Logistic regression here is analogous to an ANOVA model, but for log odds(Admit)
- (With categorical predictors, these are often called logit models)
- Every such model has an equivalent loglinear model form.
- This plot shows fitted logits for the main effects model, Dept + Gender

The Logistic Regression Model

Binary response: What's wrong with OLS?

- For a binary response, $Y \in (0, 1)$, want to predict $\pi = Pr(Y = 1 | x)$
- A linear probability model uses classical linear regression (OLS)
- Problems:
 - Gives predicted values and CIs outside $0 < \pi < 1$
 - Homogeneity of variance is violated: $V(\hat{\pi}) = \hat{\pi}(1 \hat{\pi}) \neq$ constant
 - Inferences, hypothesis tests are wrong!

Linear regression vs Logistic regression

OLS regression:

• Assume $y|x \sim N(0, \sigma^2)$

Fig. 2.1. Graphical representation of a simple linear normal regression.

y linear with x constant residual variance

Logistic regression:

Assume Pr(y=1|x) ~ binomial(p)

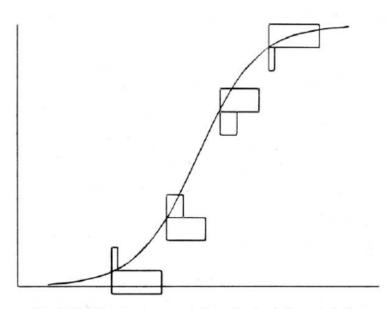

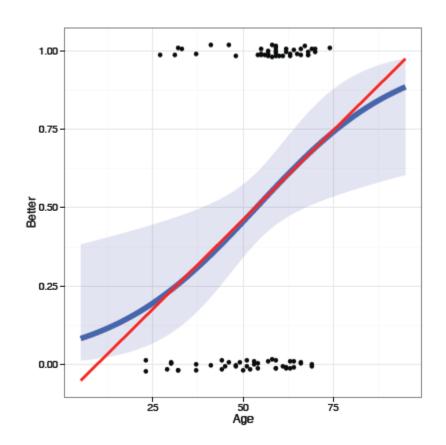

Fig. 2.2. Graphical representation of a simple linear logistic regression.

y ~ logit (x) non-constant residual variance ~ p (1-p)

Logistic regression

- Logistic regression avoids these problems
- Models $logit(\pi_i) \equiv log[\pi/(1-\pi)]$
- logit is interpretable as "log odds" that Y = 1
- A related probit model gives very similar results, but is less interpretable
- For 0.2 ≤ π ≤ 0.8 fitted values are close to those from linear regression.

Logistic regression: One predictor

For a single quantitative predictor, x, the simple linear logistic regression model posits a linear relation between the *log odds* (or *logit*) of Pr(Y = 1) and x,

$$logit[\pi(x)] \equiv log\left(\frac{\pi(x)}{1-\pi(x)}\right) = \alpha + \beta x$$
.

- When $\beta > 0$, $\pi(x)$ and the log odds increase as x increases; when $\beta < 0$ they decrease with x.
- This model can also be expressed as a model for the probabilities $\pi(x)$

$$\pi(x) = \text{logit}^{-1}[\pi(x)] = \frac{1}{1 + \exp[-(\alpha + \beta x)]}$$

Thinking logistically:

- Model is for the log odds of the marked response, Y = 1
- Can always back transform with logit⁻¹ to get probability of Y = 1

Logistic regression: One predictor

The coefficients, α , β of this model have simple interpretations in terms of odds & log odds

$$\operatorname{logit}[\pi(x)] \equiv \operatorname{log}\left(\frac{\pi(x)}{1 - \pi(x)}\right) = \alpha + \beta x \qquad \operatorname{odds}(Y = 1) \equiv \frac{\pi(x)}{1 - \pi(x)} = \exp(\alpha + \beta x) = e^{\alpha}(e^{\beta})^{x}$$

- β is the change in log odds for a unit increase in x
 - \rightarrow The odds of Y=1 are multiplied by e^{β} for each unit increase in x
- α is the log odds when x=0
 - \rightarrow The odds of Y=1 when x=0 is e^{α}

In R, use exp (coef (model)) to get these values

Another interpretation: In terms of probability, the slope of the logistic regression curve is $\beta\pi(1-\pi)$

This has the maximum value $\beta/4$ when $\pi = \frac{1}{2}$

Logistic regression: Multiple predictors

- For a binary response, $Y \in (0, 1)$, let \boldsymbol{x} be a vector of p regressors, and π_i be the probability, $\Pr(Y = 1 \mid \boldsymbol{x})$.
- The logistic regression model is a linear model for the log odds, or logit that Y = 1, given the values in x,

$$logit(\pi_i) \equiv log\left(\frac{\pi_i}{1 - \pi_i}\right) = \alpha + \mathbf{x}_i^{\mathsf{T}} \beta$$
$$= \alpha + \beta_1 \mathbf{x}_{i1} + \beta_2 \mathbf{x}_{i2} + \dots + \beta_p \mathbf{x}_{ip}$$

• An equivalent (non-linear) form of the model may be specified for the probability, π_i , itself,

$$\pi_i = \left\{1 + \exp(-[\alpha + \mathbf{x}_i^\mathsf{T} \boldsymbol{\beta}])\right\}^{-1}$$

The logistic model is also a multiplicative model for the odds of "success,"

$$\frac{\pi_i}{1 - \pi_i} = \exp(\alpha + \mathbf{x}_i^\mathsf{T} \beta) = \exp(\alpha) \exp(\mathbf{x}_i^\mathsf{T} \beta)$$

Increasing x_{ij} by 1 increases $logit(\pi_i)$ by β_i , and multiplies the odds by e^{β_i} .

Fitting the logistic regression model

Logistic regression models are the special case of generalized linear models, fit in R using glm(..., family=binomial)

For this example, we define **Better** as any improvement at all

```
> data(Arthritis, package="vcd")
> Arthritis$Better <- as.numeric(Arthritis$Improved > "None")
```

Fit and print:

The summary() method gives details and tests of coefficients

```
> summary(arth.logistic)
Call:
glm(formula = Better ~ Age, family = binomial, data = Arthritis)
Deviance Residuals:
   Min 1Q Median 3Q Max
-1.5106 -1.1277 0.0794 1.0677 1.7611
Coefficients:
           Estimate Std. Error z value Pr(>|z|)
(Intercept) -2.6421 1.0732 -2.46 0.014 *
Age 0.0492 0.0194 2.54 0.011 *
Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 '' 1
(Dispersion parameter for binomial family taken to be 1)
                                                    G^2 for H_0: \beta_{Age} = 0
   Null deviance: 116.45 on 83 degrees of freedom
                                                    G^2 for H_1: \beta_{Age} \neq 0
Residual deviance: 109.16 on 82 degrees of freedom
```

How much better is this than the null model?

$$\Delta G^{2}_{(1)} = 116.45 - 109.16 = 7.29$$

Interpreting coefficients

```
> coef(arth.logistic)
(Intercept) Age
  -2.64207 0.04925
```

```
> exp(coef(arth.logistic))
(Intercept) Age
    0.07121    1.05048
> exp(10*coef(arth.logistic)[2])
    Age
1.636
```

Interpretations:

- log odds(Better) increase by $\beta = 0.0492$ for each year of age
- odds(Better) multiplied by $e^{\beta} = 1.05$ for each year of age— a 5% increase
- over 10 years, odds(Better) are multiplied by $exp(10 \times 0.0492) = 1.64$, a 64% increase.
- Pr(Better) increases by $\beta/4 = 0.0123$ for each year (near $\pi = \frac{1}{2}$)

Multiple predictors

The main interest here is the effect of Treatment. Sex and Age are control variables. Fit the main effects model (no interactions):

$$logit(\pi_i) = \alpha + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_2 x_{i2}$$

where x_1 is Age and x_2 and x_3 are the factors representing Sex and Treatment, respectively. R uses dummy (0/1) variables for factors.

$$x_2 = \begin{cases} 0 & \text{if Female} \\ 1 & \text{if Male} \end{cases}$$
 $x_3 = \begin{cases} 0 & \text{if Placebo} \\ 1 & \text{if Treatment} \end{cases}$

- \bullet α doesn't have a sensible interpretation here. Why?
- β_1 : increment in log odds(Better) for each year of age.
- β_2 : difference in log odds for male as compared to female.
- β_3 : difference in log odds for treated vs. the placebo group

Multiple predictors: Fitting

Fit the main effects model. Use I(Age − 50) to center Age, making ② interpretable

```
arth.logistic2 <- glm(Better ~ I(Age - 50) + Sex + Treatment,
data=Arthritis, family=binomial)
```

lmtest::coeftest() gives just the tests of coefficients provided by summary()

broom::glance() gives model fit statistics

Interpreting coefficients

- $\alpha = -0.578$: At age 50, females given placebo have odds(Better) of $e^{-0.578} = 0.56$.
- $\beta_1 = 0.0487$: Each year of age multiplies odds(Better) by $e^{0.0487} = 1.05$, a 5% increase.
- $\beta_2 = -1.49$: Males $e^{-1.49} = 0.26 \times$ less likely to show improvement as females. (Or, females $e^{1.49} = 4.437 \times$ more likely than males.)
- $\beta_3 = 1.76$: Treated $e^{1.76} = 5.81 \times \text{more likely Better than Placebo}$

Hypothesis testing: Questions

• Overall test: How does my model, $logit(\pi) = \alpha + \mathbf{x}^T \boldsymbol{\beta}$ compare with the null model, $logit(\pi) = \alpha$?

$$H_0: \beta_1 = \beta_2 = \cdots = \beta_p = 0$$

One predictor: Does x_k significantly improve my model? Can it be dropped?

 $H_0: \beta_k = 0$ given other predictors retained

 Lack of fit: How does my model compare with a perfect model (saturated model)?

For ANOVA, regression, these tests are carried out using *F*-tests and *t*-tests. In logistic regression (fit by maximum likelihood) we use

- F-tests → likelihood ratio G² tests
- t-tests \rightarrow Wald z or χ^2 tests

Maximum likelihood estimation

In classical linear models using lm(), we fit using ordinary least squares. All glm() models use maximum likelihood estimation—better properties

- Likelihood, $\mathcal{L} = \Pr(data \mid model)$, as function of model parameters
- For case i,

$$\mathcal{L}_{i} = \begin{cases} p_{i} & \text{if } Y = 1 \\ 1 - p_{i} & \text{if } Y = 0 \end{cases} = p_{i}^{Y_{i}} (1 - p_{i}^{Y_{i}}) \quad \text{where} \quad p_{i} = 1 / (1 + \exp(\mathbf{x}_{i} \boldsymbol{\beta}))$$

Under independence, joint likelihood is the product over all cases

$$\mathcal{L} = \prod_{i}^{n} p_i^{Y_i} (1 - p_i^{Y_i})$$

ullet Find estimates \widehat{eta} that maximize $\log \mathcal{L}$. Iterative, but this solves the "estimating equations"

$$\boldsymbol{X}^{\mathsf{T}}\boldsymbol{y} = \boldsymbol{X}^{\mathsf{T}}\widehat{\boldsymbol{p}}$$

Overall model tests

Likelihood ratio test (G^2)

- Compare nested models, similar to F tests in OLS
- Let L_1 = maximized value for our model $logit(\pi_i) = \beta_0 + \mathbf{x}^T_i \boldsymbol{\beta}$ w/ k predictors
- Let L_0 = maximized likelihood for the null model $logit(\pi_i) = \beta_0$ under H_0 : $\beta_1 = \beta_2 = ... = \beta_k$
- Likelihood ratio test statistic:

$$G^{2} = -2\log\left(\frac{L_{0}}{L_{1}}\right) = 2(\log L_{1} - \log L_{0}) \sim \chi_{k}^{2}$$

Wald tests & confidence intervals

- Analogous to t-tests in OLS
- Test H_0 : $\beta_i = 0$

$$z = \frac{b_i}{s(b_i)} \sim \mathcal{N}(0,1)$$
 or $z^2 \sim \chi_1^2$

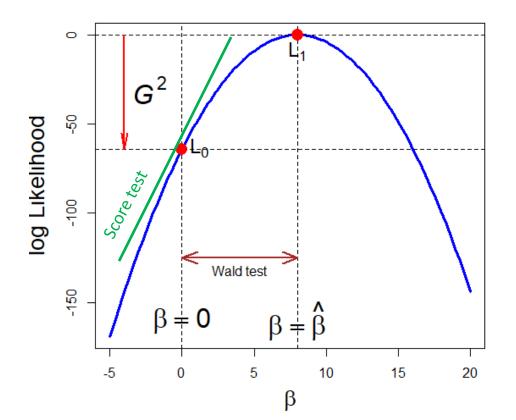

Confidence interval

$$b_i \pm z_{1-\alpha/2} s(b_i)$$

LR, Wald & Score tests

Testing	Global Null	Hypothesis:	BETA=0
Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	24.3859	3	<.0001
Score Wald	22.0051 17.5147	3 3	<.0001 0.0006

H0:
$$\beta_1 = \beta_2 = \beta_3 = 0$$

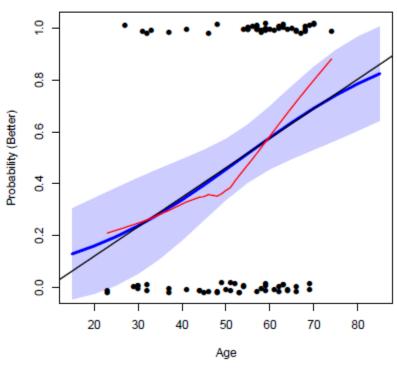

Different ways to measure departure from H_0 : $\beta = 0$

- LR test: diffce in log L
- Wald test: $(\beta \beta_0)^2$
- Score test: slope at $\beta = 0$

Plotting logistic regression data

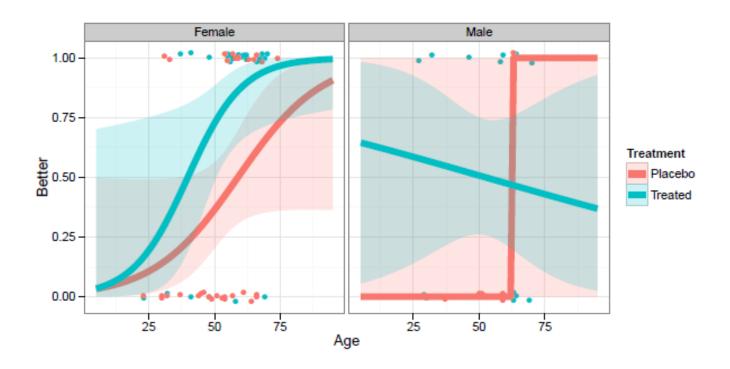

Plotting a binary response together with a fitted logistic model can be difficult because the 0/1 response leads to much overplottling.

- Need to jitter the points
- Useful to show the fitted logistic curve
- Confidence band gives a sense of uncertainty
- Adding a non-parametric (loess) smooth shows possible nonlinearity
- NB: Can plot either on the response scale (probability) or the link scale (logit) where effects are linear

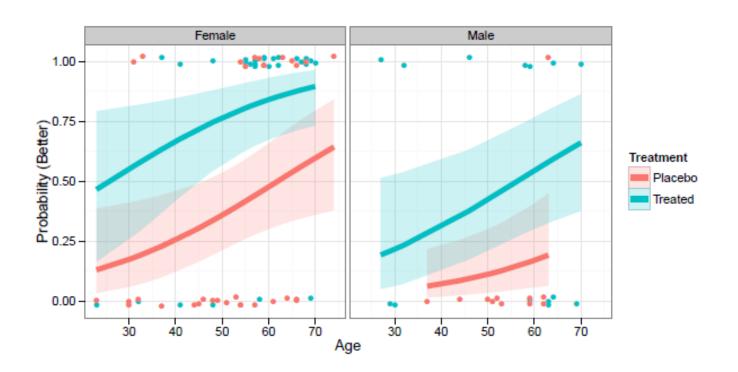

Types of plots

 Conditional plots: Stratified plot of Y or logit(Y) vs. one X, conditioned by other predictors--- only that subset is plotted for each panel

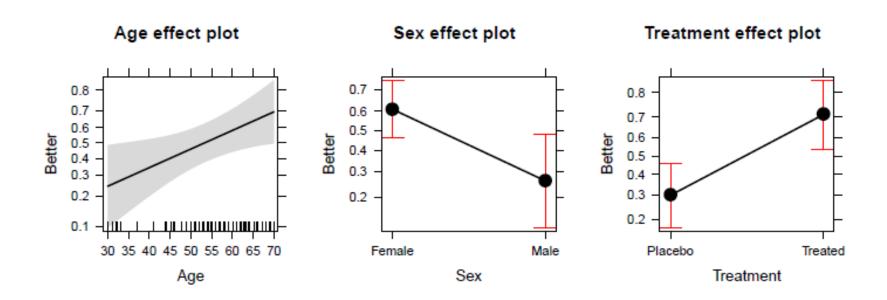

Types of plots

 Full-model plots: Plot of fitted response surface, showing all effects; usually shown in several panels

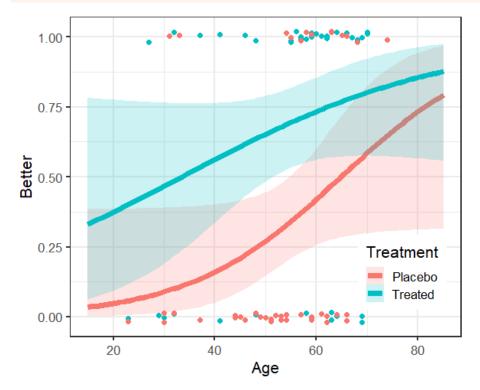

Types of plots

 Effect plots: plots of predicted effects for terms in the model, averaged over predictors not shown in a given plot

Conditional plots with ggplot2

Plot Arthritis data by Treatment, ignoring Sex; overlay fitted logistic reg. lines

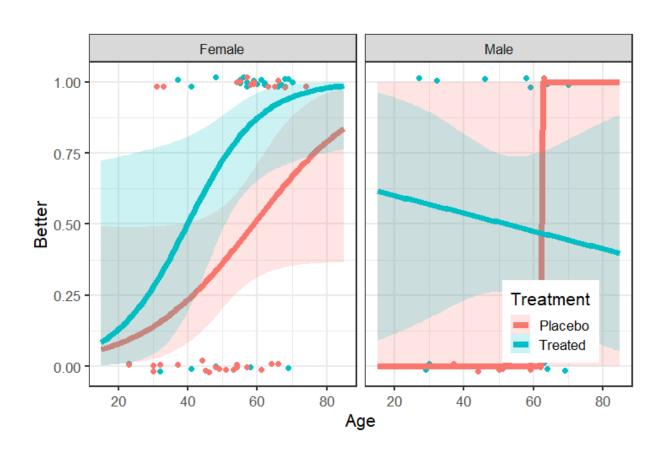

geom_jitter() shows the observations
more distinctly

Fitted lines use method="glm", family=binomial

Conditional plots with ggplot2

Can show the conditional plots for M & F, simply by faceting by Sex

Only the data for each Sex is used in each plot

Plotting the data points shows that the data for males is too thin to give good estimates of separate regression

Full-model plots

Full-model plots show the fitted values on the logit scale or on the response scale (probability), usually with confidence bands. This often requires a bit of custom programming.

Steps:

- Obtain fitted values with predict (model, se.fit=TRUE) type="link" (logit) is the default
- Can use type="response" for probability scale
- Join this to your data (cbind())
- Plot as you like: plot (), ggplot (), ···

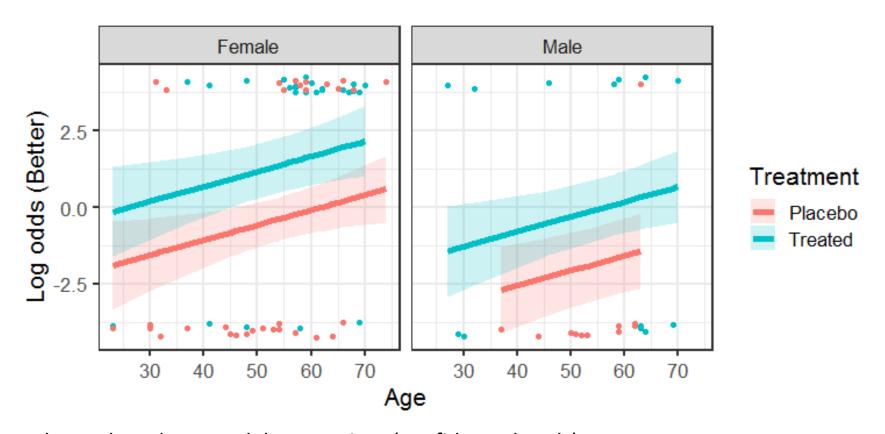

Plotting with ggplot2

Plot the fitted log odds, confidence band and observations

Using color=Treatment gives separate points and lines for the two groups

Full-model plot

Plotting on the logit scale shows the additive effects of age, treatment and sex NB: easier to compare the treatment groups within the same panel

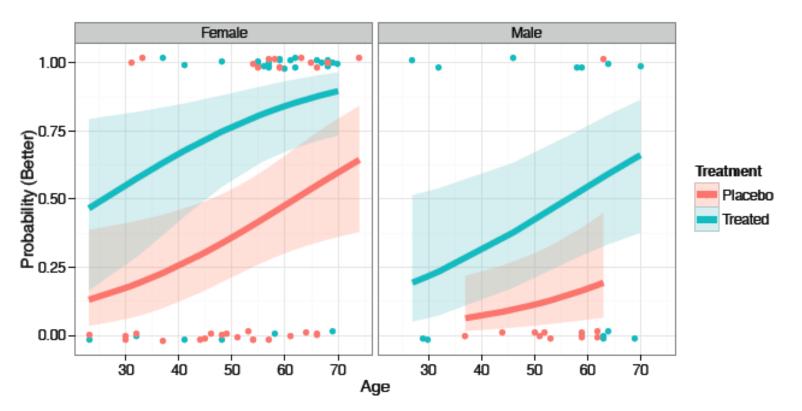

These plots show model uncertainty (confidence bands)
Jittered points show the data

Full-model plot

Plotting on the probability scale may be simpler to interpret

Use predict (... type = "response") to get fitted probabilities

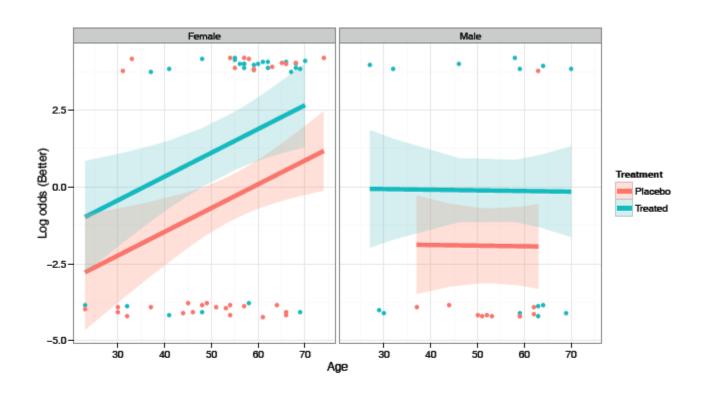

Models with interactions

Is the linear effect of age the same for females, males?

- We can test this by adding an interaction of Sex × Age
- update () makes it easy to add/subtract terms from a model
- car::Anova() gives partial tests of each term after all others

The interaction term Age: Sex is not quite significant, but plot the fitted model anyway

Models with interactions

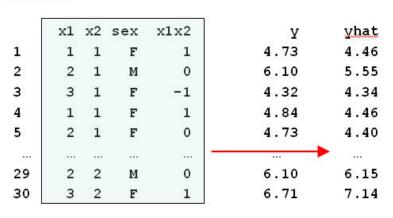

- Only the model changes
- predict () automatically incorporates the revised model terms
- Plotting steps remain the same
- This interpretation is quite different!

Effect plots: Basic ideas

Show a given marginal effect, controlling / adjusting for other model effects

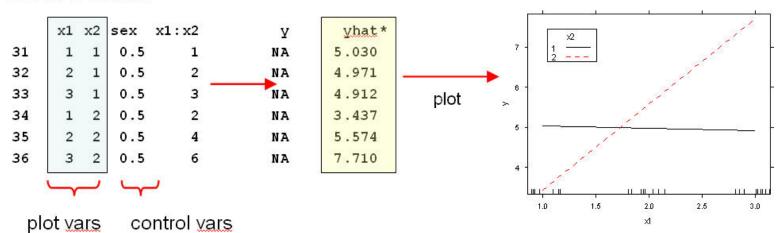

Data

- Fit data: Xβ ⇒ ŷ
- •Score data $\mathbf{X} * \hat{\mathbf{\beta}} \Rightarrow \hat{\mathbf{y}} *$
 - plot vars: vary over range
 - · control vars: fix at means

x1*x2 effect plot

Score data

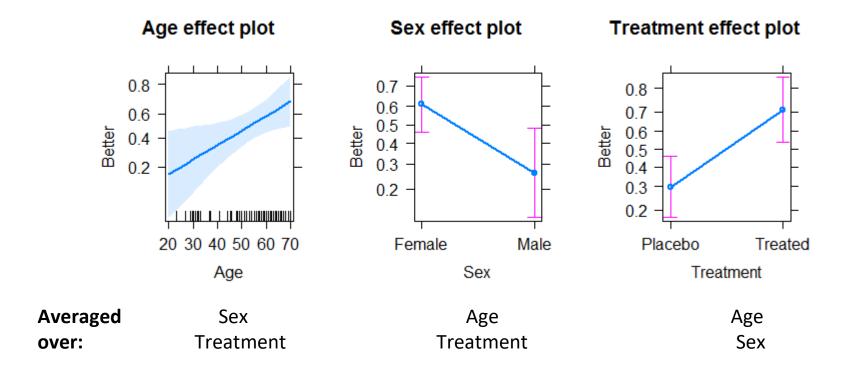

Effect plots: Details

- For simple models, full model plots show the complete relation between response and all predictors.
- Fox(1987)— For complex models, often wish to plot a specific main effect or interaction (including lower-order relatives)— controlling for other effects
 - Fit full model to data with linear predictor (e.g., logit) $\eta = \mathbf{X}\beta$ and link function $g(\mu) = \eta \to \text{estimate } \mathbf{b}$ of β and covariance matrix $\widehat{V(\mathbf{b})}$ of \mathbf{b} .
 - Construct "score data"
 - Vary each predictor in the term over its' range
 - Fix other predictors at "typical" values (mean, median, proportion in the data)
 - → "effect model matrix," X*
 - Use predict () on X*
 - Calculate fitted effect values, η̂* = X* b.
 - Standard errors are square roots of diag $X^* \widehat{V(b)} X^{*T}$
 - Plot $\hat{\eta}^*$, or values transformed back to scale of response, $g^{-1}(\hat{\eta}^*)$.
- Note: This provides a general means to visualize interactions in all linear and generalized linear models.

Plotting main effects

allEffects () calculates effects for all high-order terms in the model The response is plotted on the logit scale, but labeled with probabilities

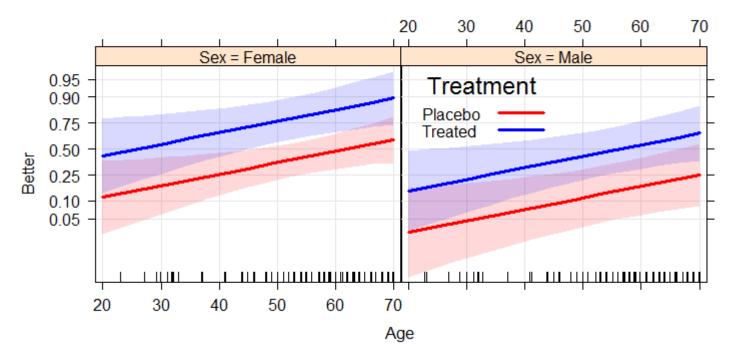

```
library(effects)
arth.eff2 <- allEffects(arth.logistic2)
plot(arth.eff2, rows=1, cols=3, lwd=2)</pre>
```

Full-model plot

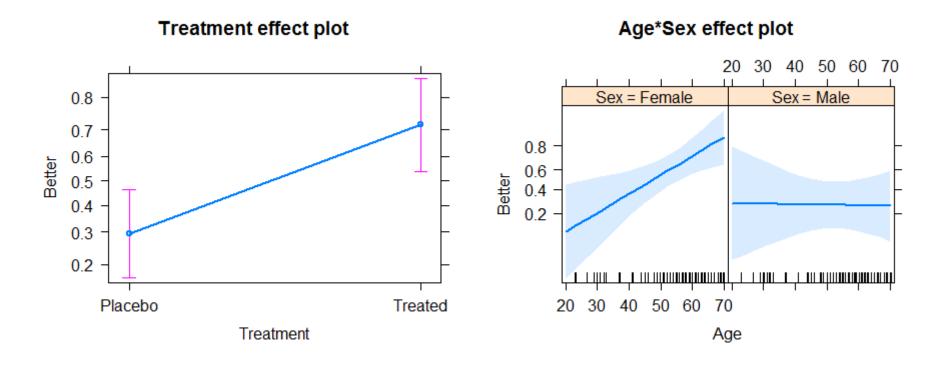

The full-model plot is simply the **Effect()** of the highest-order interaction of factors

Age*Treatment*Sex effect plot

Model with interaction of Age × Sex

```
arth.eff4 <- allEffects(arth.logistic4)
plot(arth.eff4, lwd=2)</pre>
```

Only the high-order terms: Treatment & Age * Sex are shown & need to be interpreted Q: How would you describe this?

Race & Crime

Toronto Star investigation of racial disparities in treatment by Toronto Police Services

minister

Ethics report has 'wiggle room' to

save MacAulay BY TIM HARPER

AND LES WHITTINGTON OTTAWA - Jean Chrétien receives a report from his ethics counsellor today that is expected to give him enough "wiggle room" to keep his solicitor-general, Lawrence MacAulay, in the federal cabinet,

Ethics counsellor Howard and delivered it to the Prime Minister's Office last night where it was received by Chrétien's chief of staff, Percy It was then to be relayed to Chrétien by secure fax to Bei-rut, where the Prime Minister

is attending a summit of French-speaking nations. It was 1:30 a.m. in Beirut when

the fax arrived so Chrétien

would likely be reading it this Senior sources said last night that unless there is a surprise in Wilson's report, the Prince Edward Island minister will remain, Chrétien will return to Ottawa and weather the inevi-

table storm of opposition and media protest and forge ahead

with an ethics package by mid-

ing whether MacAulay broke ethics guidelines for cabinet

ministers in the awarding of a

contract and extension worth

\$100,000 to Everett Roche, a

Charlottetown political friend

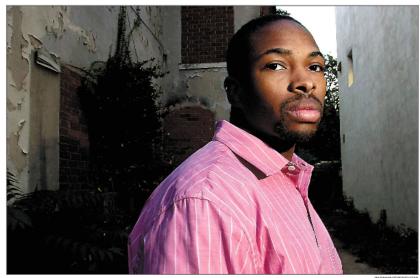

Chrétien will not fire MacAu-

lay unless he is given incontro-vertible evidence of wrongdo-

ing for two key reasons, sourc

of the solicitor-general's.

AN INVESTIGATION INTO RACE AND CRIME

SUING POLICE: Jason Burke, falsely accused of dealing drugs during Caribana two years ago, says he was a victim of racial profiling.

Singled out Star analysis of police crime data shows

Telling numbers

Police records show that a black person in Toronto arrested on a single drug possession charge was less likely to be released at the scene...

and twice as likely to be held for a ball hearing, compared to a white person on

whites, a Toronto Star analysis of crime data shows Black people, charged with simple drug possession, are taken to police stations more often than

whites facing the same charge.

Blacks arrested by Toronto po-lice are treated more harshly than

Case study: Arrests for marijuana

- In Dec. 2002, the *Toronto Star* examined the issue of racial profiling, by analyzing a data base of 600,000+ arrest records from 1997-2002.
- They focused on a subset of arrests for which police action was discretionary, e.g., simple possession of small quantities of marijuana, where the police could:
 - Release the arrestee with a summons like a parking ticket
 - Bring to police station, hold for bail, ... -- harsher treatment
- Response variable: released: "Yes", "No"
 - Main predictor of interest: skin-colour of arrestee (black, white)
 - Other predictors: year, age, sex, ...

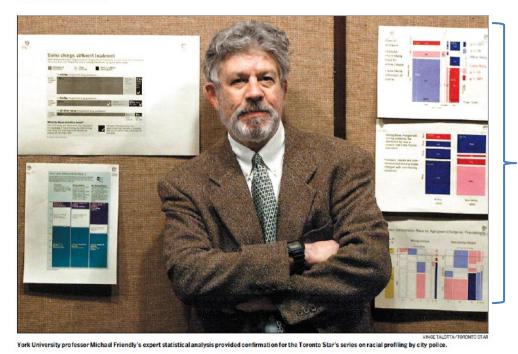

Toronto Star meets mosaic displays

How to communicate these results most effectively?

What is the message? What features are directly comprehensible to the audience?

Race and Crime

```

Effect plot: Skin colour

```
plot(Effect("colour", arrests.mod), lwd=3, ci.style="bands", ...)
```

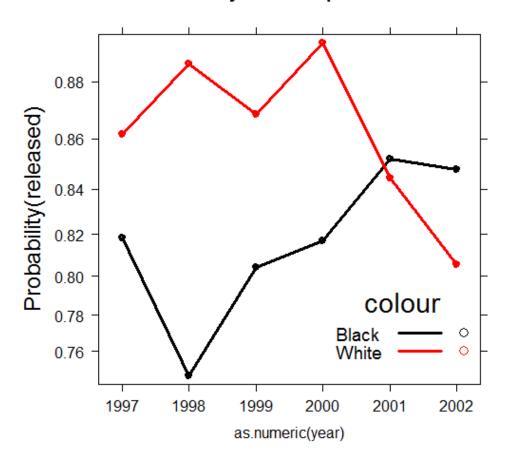

- Effect plot for colour shows average effect controlling (adjusting) for all other factors simultaneously
- (The *Star* analysis controlled for these one at a time.)
- → Evidence for different treatment of blacks & whites
- Even Francis Nunziata could understand this.
- However, effect smaller than reported by the Star

Effect plots: Interactions

The story turned out to be more nuanced than reported by the *Toronto Star*

```
plot(Effect(c("colour", "year"), arrests.mod), multiline=TRUE, ...)
```

colour*year effect plot

Up to 2000, strong evidence for differential treatment of blacks & whites

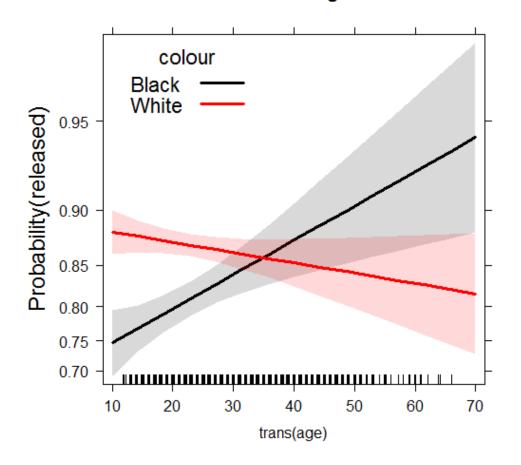

Also: evidence to support Police claim of effect of training to reduce racial effects in treatment

Effect plots: Interactions

A more surprising finding ...

```
plot(Effect(c("colour","year"), arrests.mod), multiline=TRUE, ...)
```

Effects of skin colour and age on release

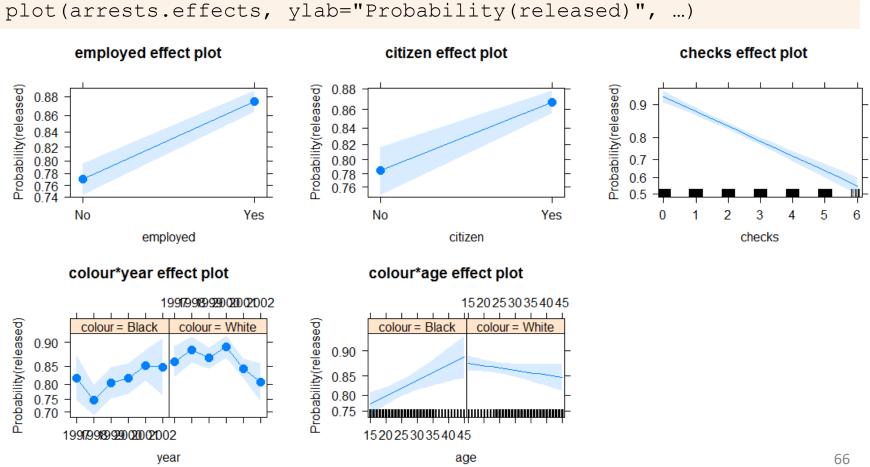

Opposite age effects for blacks & whites:

- Young blacks treated more harshly than young whites
- Older blacks treated less harshly than older whites

Effect plots: allEffects

All high-order terms can be viewed together using plot(allEffects(mod))

```
arrests.effects <- allEffects(arrests.mod,
xlevels=list(age=seq(15,45,5)))
plot(arrests.effects, ylab="Probability(released)", ...)</pre>
```

Model diagnostics

As in regression and ANOVA, the validity of a logistic regression model is threatened when:

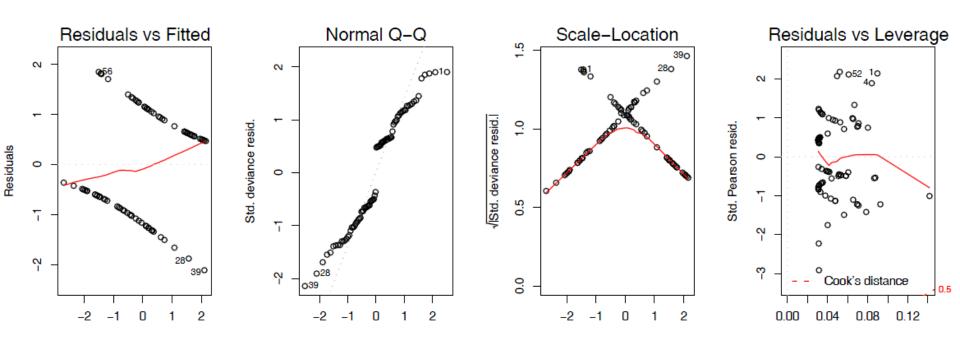

- Important predictors have been omitted from the model
- Predictors assumed to be linear have non-linear effects on Pr(Y = 1)
- Important interactions have been omitted
- A few "wild" observations have a large impact on the fitted model or coefficients

Model specification: Tools and techniques

- Use non-parametric smoothed curves to detect non-linearity
- Consider using polynomial terms (X², X³,...) or regression splines (e.g., ns (X, 3))
- Use update (model, ...) to test for interactions—formula: ...

Diagnostic plots in R

In R, plotting a glm object gives the "regression quartet" – 4 basic diagnostic plots

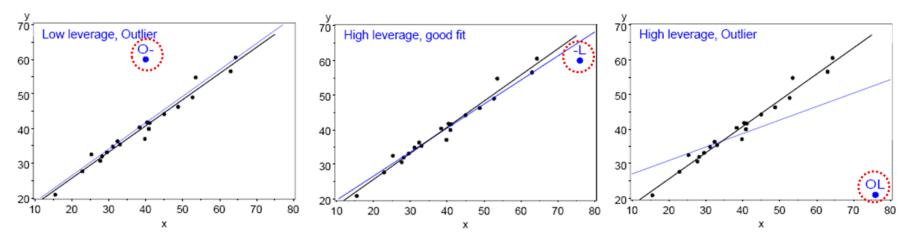

These plots often look peculiar for logistic regression models Better versions are available in the car package

Unusual data: Leverage & Influence

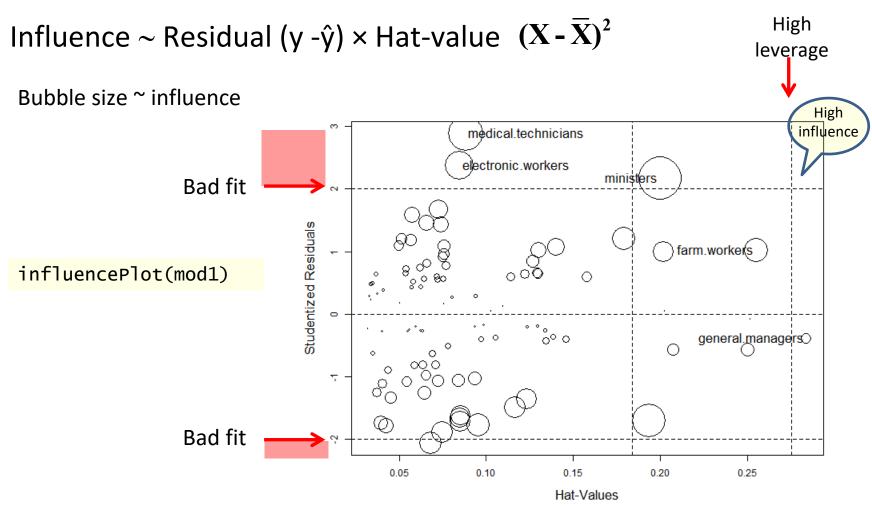

- "Unusual" observations can have dramatic effects on least-squares estimates in linear models
- Three archetypal cases:
 - Typical X (low leverage), bad fit -- Not much harm
 - Unusual X (high leverage), good fit -- Not much harm
 - Unusual X (high leverage), bad fit -- BAD, BAD, BAD
- Influential observations: unusual in both X & Y
- Heuristic formula:

Influence = X leverage × Y residual

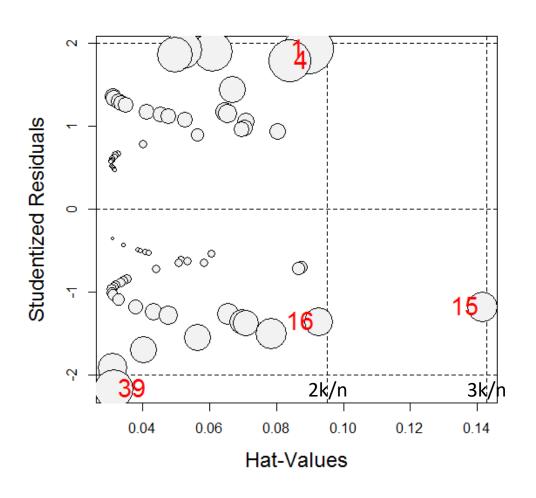

Influence plots

Influence (Cook's D) measures impact of individual obs. on coefficients, fitted values

Influence plots in R

library(car)
influencePlot(arth.logistic2, ...)

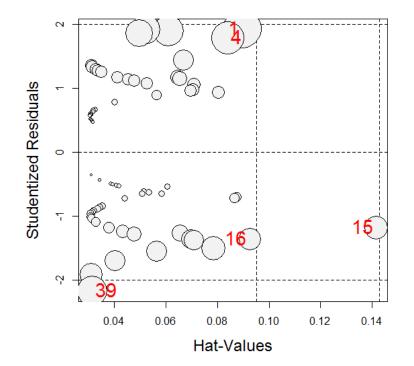

X axis: Leverage ("hat values") notable values: > 2k/n, 3k/n

Y axis: Studentized residuals

Bubble size ~ Cook's D (influence on coefficients)

Which cases are influential?

1 Treated Male 27 1 1.92 0.0897 0.1128 4 Treated Male 32 1 1.79 0.0840 0.0818 15 Treated Female 23 0 -1.18 0.1416 0.0420 16 Treated Female 32 0 -1.36 0.0926 0.0381 39 Treated Female 69 0 -2.17 0.0314 0.0690			Treatment	Sex	Age	Better	StudRes	Hat	CookD
15 Treated Female 23 0 -1.18 0.1416 0.0420 16 Treated Female 32 0 -1.36 0.0926 0.0381	1		Treated	Male	27	1	1.92	0.0897	0.1128
16 Treated Female 32 0 -1.36 0.0926 0.0381	4		Treated	Male	32	1	1.79	0.0840	0.0818
	1	5	Treated	Female	23	0	-1.18	0.1416	0.0420
39 Treated Female 69 0 -2.17 0.0314 0.0690	1	6	Treated	Female	32	0	-1.36	0.0926	0.0381
	3	9	Treated	Female	69	0	-2.17	0.0314	0.0690

case 1: younger male: moderate Hat, better than predicted → large Cook D

case 39: older female: small Hat, but did not improve with treatment

Looking ahead

- Logistic regression models need not always have linear effects— models nonlinear in Xs sometimes useful
- Polytomous outcomes can be handled as well
 - e.g., Improved = {"None", "Some", "Marked"}
- If ordinal,
 - the proportional odds model is a simple extension
 - nested dichotomies provides an alternative approach
- Otherwise, multinomial logistic regression is the way

Summary

- loglm() provides only overall tests of model fit
- Model-based methods, glm(), provide hypothesis tests, Cls & tests for individual terms
- Logistic regression: A glm() for a binary response
 - linear model for the log odds Pr(Y=1)
 - All similar to classical ANOVA, regression models
- Plotting
 - Conditional, full-model plots show data and fits
 - Effect plots show predicted effects averaged over others
- Model diagnostics
 - Influence plots are often informative
